# 1. Introduction

C# is an object-oriented programming language developed by Microsoft. It belongs to the strongly typed languages helping programmers to possibly reveal bugs at compile time. The first part of this thesis focuses on exploring type systems of strongly typed languages and proposes an improvement to the C# type system. The second part concerns the implementation of the improvement in the current C# compiler and the creation of a proposal that has sufficient potential to be discussed by the Language Design Team (LDT) accepting new C# language features.

## 1.1 Improving C# type system

A key feature of strongly typed languages is type safety, prohibiting operations on incompatible data, achieved by determining data types at compile time. The easiest way for a compiler to reason about types of variables in the code is by providing type annotations determining the data type that these variables hold. Figure 1.1 shows an usage of type annotations given by a programmer written in the C# programming language. The type declaration of the `people` variable guarantees that the following attempt to concatenate the "Tom" string to that variable will be reported as an error at compile time since the operation is not defined for a pair of the `List<string>` type and `string` type.

```
List<string> people = new List<string>() {"Joe", "Nick"};
people += "Tom"; // Error reported during compilation
```

Figure 1.1: Type safety in the C# programming language.

On the other hand, the programmer has to write more code to annotate the variable declaration and object creation whose type has a long name, as we can see in the example. This disadvantage of strongly typed languages can be removed by *type inference* when a missing type annotation can be deduced using the context. Taking the example shown above, one of the `List<string>` type annotations could be removed since the type of `people` variable declaration can be deduced from its initializing value or the type of object creation can be deduced from the type of the assigning variable. There is an example of C# type inference in Figure 1.2, where the `var` keyword is used to trigger type inference determining a type of `people` variable to be the `List<string>` type.

```
var people = new List<string>();
```

Figure 1.2: Type inference in the C# programming language.

The power of type inference varies in strongly typed languages. An example of the difference can be seen in type arguments deduction of generic methods. In the context of C#, a generic method is a method that is parametrized by types besides common parameters, as can be found in Figure 1.3. There is a generic method `GetField` enabling to return a value of `o`'s field with the `fieldName`

```

T GetField<T>(object o, string fieldName) { ... }

object person = ...
string name = GetField<string>(person, "name");

```

Figure 1.3: C# Type inference of generic methods.

name. The type of returned value is generic parameter `T` since it depends on the type of object's field. The `name` variable is initialized by using the method to retrieve a `person`'s name, which is supposed to be a string. There is a redundancy in that statement since the type argument list of the `GetField` method could be removed, and `T` could be deduced from the type of `name` variable, which has to be compatible with the return type. However, the current version of C# type inference fails to deduce it.

A similar concept of generic methods was introduced in the Rust [22] programming language, which belongs to strongly type languages too. Figure 1.4 shows a definition of the generic method `GetField`, which is equivalent to the C# method mentioned in the previous example. There is an equivalent initialization of `name` variable declaration starting with the `let` keyword, where Rust type inference deduces the type argument `T` to be the `&str` type utilizing the type information from the `name` variable declaration.

```

fn GetField<T>(o: &object, fieldName: &str) -> T { ... }

let person: &object = ...;
let name: &str = GetField(person, "name");

```

Figure 1.4: Rust Type inference of generic methods.

Although Rust is younger than C# and has a different type system, it managed to make type inference more powerful in the context of strongly typed languages to significantly save type annotations typing. The first goal of this thesis is to investigate if the same level of type inference can be achieved in C# and improve C# type inference to be used in more scenarios saving type annotations typing.

The investigation explores type system requirements and type inference differences to achieve a desired level of type inference by formalizing Rust and C# type inference. These formalizations can be partially identified as a part of the existing Hindley-Millner [24] type inference formalization, which helps to reason about the inference in these languages. Traditional Hindley-Millner type inference is defined in the Hindley-Millner type system [23], where it can deduce types of all variables in an entirely untyped code. The power of type inference is caused by properties of the type system, which, in comparison with the C# type system, doesn't use type inheritance or overloading. Despite the differences, Hindley-Millner type inference can be modified to work with other type systems like Rust or C#, causing limited use cases where it can be applied. Observing the influence of differences between these type systems on type inference will help to understand a limitation of possible type inference improvement in C#.

## 1.2 Implementation

The first part of the thesis explores limitations of C# type inference and proposes an improvement. The first goal of the second part tests the improvement by implementing it in an official C# compiler, Roslyn [18], which is an open-source project managed by Microsoft. The prototype is used to explore potential implementation issues which the improvement can cause, and that helps to adjust the improvement to be potentially enabled in the C# compiler.

Although the compiler is managed by the company, it has an open-source development, which makes contributions from interested people possible to be merged into the production. Although it is sufficient to make a *pull request* containing a fix for solving compiler issues to be merged, language design improvements, similar to what the thesis proposes, require a special process of validating the actual benefit. The process starts by proposing new C# features in public discussions of the C# language repository [18], where everyone can add his ideas or comment on others' ideas. It is preferred to use a predefined template [20] for describing the idea proposing the feature in order to make the idea more likely to be discussed by the team responsible for accepting new language features. The template includes motivation, detailed description, needed C# language specification [19] changes, and other possible alternatives. The second goal of this part is to create the improvement as the language proposal, which would be presented to the team in order to have the potential to be a part of the current C# language. The process of language proposal ends with LDT accepting or declining it.

## 1.3 Summary

We summarize goals of this thesis in the following list:

- G1. Explore possibilities of type inference in strongly typed languages
- G2. Improve C# type inference based on previous analysis
- G3. Implement the prototype in Roslyn
- G4. Create an proposal containing the improvement

## 2. Related work

The introduction presented the programming language C# and its possible improvement of type inference. This chapter continues by describing relevant sections of the C# language and its type inference algorithm to understand the possible barriers to implement improved type inference. A primary source of inspiration for the improvement is Hindley-Milner type inference, which is explored in more detail with references to its modification in Rust and C# programming languages. In the end, the chapter mentions relevant C# language issues presented on the GitHub repository, which is used later to prioritize the improvement features to make it more likely to be discussed at Language Design Meetings (LDM) held by LDT.

### 2.1 C# programming language

Since type inference is a complicated process touching many areas of the C# language, this section firstly sorts these areas into separated groups described in necessary detail to understand all parts of the current type inference. These areas concern the C# type system, including generics and language constructs where the type inference occurs or interacts with.

#### 2.1.1 Type system

C# data types are defined in the C# type system, which also defines relations between them. The most fundamental relation is type inheritance, where every type inherits another type, forming a tree with `System.Object` as a root node that doesn't inherit any type. Types are divided into value and reference types, shown in Figure 2.1, where an arrow means *is inherited by* relation. Value types consist of built-in numeric types referred to as *simple types*, and enumerations referred to as *enum types*, structures referred to as *struct types*, and nullable types. Compared to reference types, value types are implicitly sealed, meaning that they can't be inherited by other types. Reference types consist of interfaces, classes, arrays, and

Figure 2.1: The C# data types schema adjusted from a C# blog[11].

delegates. An interface introduces a new relation to the type system by defining a list of methods, called a contract, which has to be implemented by a type that implements the interface. The relation forms an acyclic graph, meaning a type can implement multiple interfaces, but the implementation relations can't form a cycle. Delegates represent typed pointers to methods describing its signature, including generic parameters, parameters, and a return type.

The type system implicitly allows to assign `null`, indicating an invalid value, to reference types. Since C# 2.0 [13], it allows to assign `null` value to nullable types, which are equivalents of the rest of value types prohibiting it. Because assigning `null` value is referred to as a billion-dollar mistake, C# 8.0 [13], introduced optional settings warning about assigning null values and created nullable reference types, which, together with nullable types, explicitly allows `null` assignment as a way of interaction with legacy code not using the feature.

A big part of the type system is C# *generics*, allowing the parameterization of types and methods by arbitrary types. A specific generic method or type is *constructed* by providing required type arguments, where *construction* means replacing all occurrences of type parameters with the type arguments. Since type argument can be arbitrary type, the type parameter is considered to be the most general type in the type system, `System.Object`. Assuming additional API from the type parameter is achieved by restricting a set of types, which can replace the type parameter, enabling a specific interface of this set. The restriction is described by type constraints, which can be applied to type parameters. There are several kinds of constraints that can be combined together, forcing the type argument to fulfill all of them. Figure 2.2 shows only two of them, and the rest can be found in the C# documentation [15]. There is a definition of the `PrioritySorter` generic class with the `TItem` type parameter containing two constraints that the type argument has to hold. The `class` constraint allows only reference types. The `IPriorityGetter` constraint allows only types that implement the interface.

```
class PrioritySorter<TItem> where TItem : class, IPriorityGetter
{ ... }
```

Figure 2.2: C# type constraints.

Constructed methods and types are new entities that don't have any special relations between themselves implied from the construction. However, C# generic interfaces can utilize a concept of type variance to introduce additional relations between constructed types. Initially, type parameters are *invariant*, meaning an obligation to use the same type arguments as initially required. A type parameter can be specified to be *covariant*, by prepending the type parameter declaration with the `in` keyword, allowing to use more derived type than initially required. Opposite *contravariance* uses the `out` keyword, allowing to use more general type than initially required.

The last relevant feature of the type system is method overloading, which allows definitions of multiple methods with the same name, return type, and count of type parameters having different types of parameters. Further chapters will mention the feature as an obstacle in designing efficient type inference.

## 2.1.2 Relevant constructs

This section mentions unrelated C# constructs where type inference occurs or influences the type inference algorithm. Their internals are then considered in the following chapters regarding the design of the improvement.

### Dynamic

Introduction 1.1 mentioned that strongly typed languages require knowing data types at compile time to prohibit incompatible operations on them. In the context of C#, data means values of expressions that are transformed by operations defined on their types. It turned out that operations on expressions of unknown type at compile time became crucial for interoperability with other dynamic-typed languages whose types of expressions are known at runtime. To make the interoperability easier, C# introduced the **dynamic** type that can be used as an ordinary type, which avoids the checks and causes *dynamic binding*. *Binding* is a process of resolving referenced operations based on the type and value of the expression. The majority of the C# binding happens statically at compile time. Expressions containing a value of the **dynamic** type are dynamic bound at runtime, bypassing the static binding of the compiler. This behavior can lead to possible bugs regarding invalid operations on the dynamic data types, which will be reported during runtime. Figure 2.3 shows a declaration of the **a** variable of the dynamic type. Dynamic binding occurs in the **a.Foo()** expression, where the **Foo()** operation is not checked during compilation. An error is reported at runtime when the actual type of the **a** variable is determined to be **string**, which doesn't define **Foo()** operation. Despite the dynamic binding, a compiler can still little check certain kinds of expressions containing values of dynamic types to reveal possible errors at compile time. An example of such checking is the **Bar()** method call, where the compiler can check the first argument, whose type is known at compile time as the type of the parameter. An appropriate error occurs during the compilation because string value has the **string** type, and it is passed as the **textt1p1** parameter, which has the **int** type.

```
dynamic a = "string";
a.Foo();
Bar("string", 1, a); \\ Compilation error reported

void Bar<T>(int p1, T p2, long p3) {...}
```

Figure 2.3: C# dynamic type.

### Anonymous function

C# allows to define a function without a name, called *anonymous function*. The function is represented as an expression that can be called or stored in a variable. There are three types of anonymous function. The first type is *anonymous method* shown in Figure 2.4 where it is stored in the **a** variable. The **b** variable contains the second type called *explicit typed anonymous function*. The third variable **c** contains the last type called *implicit typed anonymous function*. As can be seen,

all of them have inferred return types based on return expression inside their bodies. The most interesting type is the last one, where even parameter types are inferred based on a surrounding context and which is especially threatened by *method type inference* algorithm mentioned in Type inference section 2.1.3.

```
Func<int, int> a = delegate(int p1) { return p1 + 1; };  
Func<int, int> b = (int p1) => { return p1 + 1; };  
Func<int, int> c = (p1) => { return p1 + 1; };
```

Figure 2.4: C# anonymous functions.

## Object creation expression and initializer

Initializers are used as a shortcut during an object instantiation. The simplest one is *object initializer* allowing to assign values to the object's fields pleasantly instead of assigning them separately after the initialization. The second type of initializers regards arrays and collections. *Array initializers* are used to create fixed-size arrays with predefined content. Figure 2.5 shows the `arrayInit` variable initialized by an array of `int` with two items using the initializer. Under the hood, each item in the initializer is assigned to the corresponding index of the array after the array creation. *Collection initializers* are similar to array initializers defined on collections, which are created by implementing `ICollection<T>` interface. One of the interface's declaring methods is `void Add<T>(T)` with adding semantics. Each type implementing this interface is allowed to use an initializer list in the same manner as an array initializer. It's just a sugar code hiding to call the *Add* method for each item in the initializer list. The last type of an initializer uses an indexer to store referred values on predefined positions, which is used in the second statement where the `indexerInit` variable is initialized by a dictionary object using indexers in its initializer list.

```
var arrayInit = new int[] { 1, 2 };  
var indexerInit = new Dictionary<string, int>() {  
    ["a"] = 1, ["b"] = 2  
};
```

Figure 2.5: C# collection initializer.

### 2.1.3 Type inference

C# type inference occurs in many contexts. However, this section mentions only these related to our improvement described in the following chapters.

#### Keyword `var`

One of the simplest type inference occurrences regards the `var` keyword used in a variable declaration. It lets the compiler decide the type of variable based on the type of initializing value, which implies that it can't use the keyword in declarations without initializing the value. Figure 2.6 shows the usage, where the

type of the `a` variable is determined to be `string` since it is initialized by a string value.

```
var a = "str";
```

Figure 2.6: Keyword `var`.

### Operator `new()`

There is also an opposite way of deducting types from a target to a source. An example is the `new()` operator, which can be called with arbitrary arguments and represents object creation of a type that is determined by a type of the target. An example of these situations can be seen in Figure 2.7 where the target-typed `new(1)` operator allows to skip the specification of creating type in the object creation expression since the `myList` variable type gives it. After the type inference, the operator represents the new `new List<int>(1)` object creation expression.

```
List<int> myList = new(1);
```

Figure 2.7: Operator `new()`.

### Method type inference

Method type inference is the most complex C# type inference used during generic method call binding when type arguments are not given. Figure 2.8 shows a situation when the method type inference deduces `System.String`, `System.Int32` and `System.Int32` as type arguments of the `Foo` method. There is a multi-step process that the type inference has to do to be able to infer it. Regarding the `T1` type parameter, the inference has to find a common type between the `(long)1` argument and the `(int)1` argument. Regarding the `T2` type parameter, the type inference has to go into type arguments of the generic type of the `p3` parameter and the `myList` argument, check if the types are compatible, and then match the `T2` type parameter against the `int` type argument of the `List<int>`. The `T3` type parameter is the most challenging since it occurs as a return type of the delegate. The type inference has first to infer types of input parameters of this delegate to be able to infer the implicit anonymous function's return type. Then, it can match the inferred return type with the `T3` type parameter, resulting in the `System.Int32` type.

```
List<int> myList = ...  
Foo((long)1, (int)1, myList, (p1) => p1 + 1);  
  
Foo<T1, T2, T3>(T1 p1, T1 p2, IList<T2> p3, Func<T2, T3> p4) {...}
```

Figure 2.8: Method type inference.

Since one of the thesis's improvements is adjusting the algorithm, this section presents its description. The thesis doesn't show the complete algorithm

described in the C# specification [14] since it is complex, and some sections are unimportant for the following chapters. The simplified algorithm is divided into four separate figures. Before describing the algorithm, the section presents definitions used by the algorithm.

**Definition 1** (Fixed type variables, bounds). *We call inferred type parameters type variables which are at the beginning of the algorithm unknown, unfixed. During the algorithm, they start to be restricted by sets of type bounds. The type variable becomes fixed when the its actual type is determined using its bounds.*

**Definition 2** (Method group). *A method group is a set of overloaded methods resulting from a member lookup.*

**Definition 3** (Input/Output types). *If  $E$  is a method group or anonymous function and  $T$  is a delegate or expression tree type, then return type of  $T$  is an output type of  $E$ . If  $E$  is a method group or implicitly typed anonymous function, then all the parameter types of  $T$  are input types of  $E$ .*

**Definition 4** (Dependence). *An unfixed type variable  $X_i$  depends directly on an unfixed type variable  $X_e$  if for some argument  $E$   $X_e$  occurs in an input type of  $E$  and  $X_i$  occurs in an output type of  $E$ .  $X_i$  depends on  $X_e$  is the transitive but not reflexive closure of depends directly on.*

<code>{Parameter}.isValParam</code>	Checks if the parameter is passed by value.
<code>{Parameter}.isRefParam</code>	Checks if the parameter is passed by reference.
<code>{Parameter}.isOutParam</code>	Checks if the parameter has <b>out</b> modifier.
<code>{Parameter}.isInParam</code>	Checks if the parameter has <b>in</b> modifier.
<code>{Argument}.isInArg</code>	Checks if the argument has <b>in</b> modifier.
<code>{Type}.outTypes</code>	Returns <i>Output</i> types of type.
<code>{Type}.inTypes</code>	Returns <i>Input</i> types of type.
<code>{Type} isLike '{Pattern}'</code>	Checks if the type matches the pattern.
<code>{Type}.isDelegateOrExprTreeType</code>	Checks if the type is Delegate or Expression Tree type.

Table 2.1: Description of used properties.

The pseudocode used to describe the algorithm uses custom helper functions explained in 2.1. Figure 2.9 shows the initial phases of the algorithm. The method type inference process starts with receiving arguments of a method call and the method's signature, which type parameters have to be deduced. The algorithm has two phases, where the first phase initializes initial bounds' sets of type variables(inferred type arguments), and the second phase repeats until all type variables are fixed or fail if there is insufficient information to deduce

them. Each type variable has three types of bounds. The exact bound consists of types, which have to be identical to the type variable, meaning that they can be converted to each other. The lower bound contains types that have to be convertible to the type variable, and the upper bound is opposite to it.

```

1 Input: method call  $M(E_1, \dots, E_x)$  and
2       its signature  $T_e M\langle X_1, \dots, X_n \rangle (T_1 p_1, \dots, T_x p_x)$ 
3 Output: inferred  $X_1, \dots, X_n$ 
4  $B_{lower} = B_{upper} = B_{exact} = F = []$ 
5 FirstPhase()
6 SecondPhase()
7 fn FirstPhase():
8   E.foreach(e →
9     if (e.isAnonymousFunc)
10      InferExplicitParamterType(e, T[e.idx])
11   elif (e.getType() is Type u)
12     switch (u) {
13       p[e.idx].isValParam → InferLowerBound(u, T[e.idx])
14       p[e.idx].isRefParam || p[e.idx].isOutParam →
15         InferExact(u, T[e.idx])
16       p[e.idx].isInParam && e.isInArg →
17         InferLowerBound(u, T[e.idx])
18     }
19   )
20 fn SecondPhase():
21   while (true):
22      $X_{indep} = X.filter(x →$ 
23        $F[x.idx] == \text{null} \ \&\& \ X.any(x → dependsOn(x, y))$ 
24      $X_{dep} = X.filter(x →$ 
25        $F[x.idx] == \text{null} \ \&\& \ X.any(y →$ 
26          $dependsOn(y, x) \ \&\& \ (B_{lower} + B_{upper} + B_{exact}).isEmpty)$ 
27     switch {
28        $X_{indep}.isEmpty → X_{indep}.foreach(x → Fix(x))$ 
29        $X_{dep}.isEmpty \ \&\& \ X_{indep}.isEmpty → X_{dep}.foreach(x → Fix(x))$ 
30        $(X_{indep} + X_{dep}).isEmpty →$ 
31         return if ( $F.any(x → x == \text{null})$ ) Fail() else Success(F)
32       default →  $E.filter(e →$ 
33          $X.any(x →$ 
34            $F[x.idx] == \text{null} \ \&\& \ T[e.idx].outTypes.contains(x))$ 
35          $\ \&\& \ !X.any(x →$ 
36            $F[x.idx] == \text{null} \ \&\& \ T[e.idx].inTypes.contains(x))$ 
37          $).foreach(e → InferOutputType(e, T[e.idx]))$ 
38       }

```

Figure 2.9: Phases of Method Type Inference

`FirstPhase()` iterates over provided arguments and matches their types with types of corresponding parameters. This matching has two goals. The first is to check the compatibility of matched types, and the second is to collect the men-

tioned bounds associated with type variables contained in parameters' types. This matching has many rules, followed by helping functions mentioned later in this section. The matching represents dealing with the T2 type parameter mentioned in the example where the compatibility between `List<int>` and `IList<T2>` is firstly checked, and then the `int` type is added as a lower bound of the T2 type parameter. Type variables can have dependencies between themselves, so the first phase postpones matching output types of arguments' types with corresponding parameters' types because the output types can contain dependent type variables.

`SecondPhase()` happens iteratively, respecting the *depends on* relation. Each iteration has two goals. The first one is the fixation of at least one type variable. If there is no type variable to fix because either all type variables are fixed or there are no other type bounds that could be used for type variable deduction, the algorithm ends. The sets  $X_{indep}$  and  $X_{dep}$  refer to type variables, which can be fixed in the current iteration. Line 31 contains the ending condition of the algorithm when all type variables are fixed, or there is no way to infer the next ones. The second goal is to match postponed matching of output types of arguments' types with output types of corresponding parameters' types where all type variables in the output type of a parameter type don't depend on unfixed variable types contained in input types of the parameter type. The second goal is to match postponed matching of output types of arguments' types with output types of corresponding parameters' types where all type variables in the output type of a parameter type don't depend on unfixed variable types contained in input types of the parameter type. Line 32 describes this process using the pseudocode. This goal represents dealing with implicit anonymous functions mentioned in Figure 2.8 where T3 depends on T2. The algorithm first infers the T2 input type of the anonymous function, then infers the function's output type, which is then used to match the output type of `Func<T2, T3>` parameter type with the output type of the inferred anonymous function's type. The match yields the `int` upper bound of the T3 type parameter.

```

1  fn InferExplicitParameterType(Argument E, Type T):
2      if (E.isExplicitTypedAnonymousFunc && T.isDelegateOrExprTreeType
3          && E.paramTypes.size == T.paramTypes.size)
4          E.paramTypes.zip(T.paramTypes)
5              .foreach((e, t) → InferExact(e, t))
6  fn InferOutputType(Argument E, Type T):
7      switch(E) {
8          E.isAnonymousFunc && T.isDelegateOrExprTreeType →
9              InferLower(InferReturnType(E), T.returnType)
10         E.isMethodGroup && T.isDelegateOrExprTreeType → {
11             E_resolved = OverloadResolution(E, T.parameterTypes)
12             if (E_resolved.size == 1)
13                 InferLower(E_resolved[0].returnType, T.returnType)
14         }
15         E.isExpression && E.getType() is Type u → InferLower(u, T)
16     }

```

Figure 2.10: *Explicit parameter type inference, Output type inference*

Figure 2.10 contains definitions of two helper functions used in the first and second phases. The `ExplicitParameterType()` function is used to match an argument type, which is an explicit typed anonymous function. This function has typed parameters, so the algorithm matches them with input types of the corresponding parameter type.

The `InferOutputType()` function is used in the second phase when postponed matching of output types happens. Because potential type variables contained in the return types don't depend on any unfixed type variables, the algorithm can match them. There are two situations where the output type is matched. The first situation regards anonymous functions, where the algorithm first infers the return type represented by the `InferReturnType()` function and then matches it with the output type of the corresponding parameter. The second situation regards method groups, which are firstly resolved by `OverloadResolution()`. The return type of the resolved method is matched with the output type of the corresponding parameter.

```

1 fn InferExact(Type U, Type V):
2   if (X.any(x → V == x && F[x.idx] == null)) Bexact[i].add(U)
3   switch(V) {
4     V isLike 'V1[...]' && U isLike 'U1[...]' && V.rank == U.rank →
5       InferExact(U1, V1)
6     V isLike 'V1?' && U isLike 'U1' → InferExact(V1, U1)
7     V isLike 'C<V1, ..., Ve>' && U isLike 'C<U1, ..., Ue>' →
8       V.typeArgs.zip(U.typeArgs)
9         .foreach((v, u) → InferExact(v, u))
10  }
11 fn InferLower(Type U, Type V):
12   if (X.any(x → V == x && F[x.idx] == null)) Blower[i].add(U)
13   switch { .... }
14 fn InferUpper(Type U, Type V):
15   if (X.any(x → V == x && F[x.idx] == null)) Bupper[i].add(U)
16   switch { ... }

```

Figure 2.11: *Exact inference, Upper-bound inference, Lower-bound inference*

Figure 2.11 shows three functions that add new bounds to type variables' bound sets. Basically, all of them have similar behavior. It traverses the given `U` type contained in the argument type with the `V` type contained in the corresponding parameter type using the conditions contained in the `switch` statement and adds the `U` type to the type variable's bound when the `V` type is a type variable. Since the branching conditions in `InferLower` and `InferUpper` are similar to those in `InferExact` and unimportant for the proposed improvement, the thesis omits it.

An interesting fact about adding new bounds is that there is no need to check possible contradictions because they are checked in the type variable fixation. The second observation that will be important for the following chapters is the absence of unfixed type variables in bound sets, making the algorithm easier. The reason for that can be noticed in the design of functions API, where the left parameter always contains an expression or type from the argument, and

the right parameter contains a type from the inferring method parameter. Since the three last-mentioned functions add only the type from the left parameter to bounds, there can't be any type variables because argument types don't contain type variables.

The last part of this algorithm is type variable fixation, shown in Figure 2.12. Initially, a set of candidates for the type variable is constructed by collecting all its bounds. Then, it goes through each bound and removes the candidates who do not satisfy the bound's restriction. If there is more than one candidate left, it tries to find a unique type that is identical to all left candidates. The fixation is successful if the candidate is found. The type variable is fixed to that type. This process can be seen in the initial example 2.8, where the T1 type variable contains `long` and `int` in its lower bound set. At the start of this process, both types are candidates. However, `int` is removed because it doesn't have an implicit conversion to `long`.

```

1  fn Fix(TypeParameter x):
2      U_candidates = B_lower[x.idx] + B_upper[x.idx] + B_exact[x.idx]
3      B_exact[x.idx].foreach{b →
4          U_candidates.removeAll(u → !b.isIdenticalTo(u))}
5      B_lower[x.idx].foreach{b →
6          U_candidates.removeAll(u → !hasImplicitConversion(b, u))}
7      B_upper[x.idx].foreach{b →
8          U_candidates.removeAll(u → !hasImplicitConversion(u, b))}
9      temp = U_candidates.filter(x → U_candidates.all(y →
10         hasImplicitConversion(y, x)))
11     if (temp.size == 1) F[i] = temp[0] else Fail()

```

Figure 2.12: Fixing of type variables

An important observation of the method type inference is an obligation of inferring all type arguments of the method. If the compiler is not able to infer all type arguments, an user has to specify all type arguments. C# currently doesn't offer a way how to hint just ambiguous type arguments.

## Array type inference

The last mentioned type inference happens in array initializers when the array type should be deduced from the initializer list. Figure 2.13 shows an example of a situation when the type inference is used for determining the `object[]` type of the `myArray` array. The C# specification calls it *common type inference*, which finds the most specialized common type between given types. From one point of view, it is just adjusted the already mentioned method type inference algorithm where there is just one type variable, and all initializer items are lower bounds of that type variable.

```
var myArray = new[] {new object(), "string"};
```

Figure 2.13: Array type inference.

## 2.2 Roslyn

The implementation of C# type inference can be found in the Roslyn compiler, as open-source C# and VisualBasic compiler developed at the GitHub repository. This section presents Roslyn's architecture to better understand the context and restrictions that has to be considered to plug the improved type inference into the compiler.

Figure 2.14 shows the compilation pipeline, described in Microsoft documentation [21]. The pipeline starts with loading the `.csproj` file with related C# sources (`.cs`) and referenced libraries (`.dll`). C# sources are passed to the lexer, creating tokens used by the parser forming Abstract Syntax Tree (AST). AST construction is the first phase (green boxes in Figure ??) of the compiler checking syntax of C# sources.

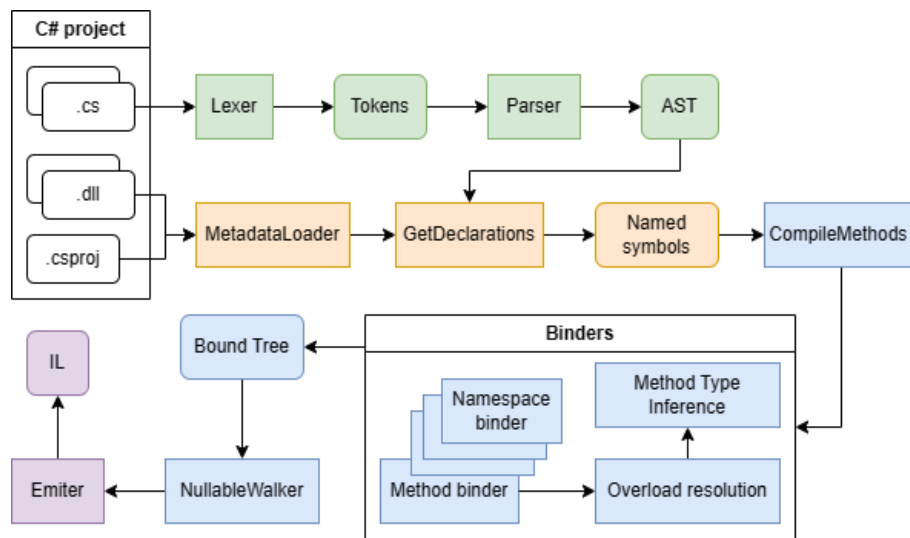

Figure 2.14: Roslyn architecture

The second phase, marked by orange, forms *named symbols* exposed by public API representing defined namespaces, classes, methods, etc., in the C# project. The declarations are received from C# sources by traversing AST and seeking for the particular syntax. Libraries, stored in `.dll` format are parsed by `MetadataLoader`, creating the same named symbols as those received from C# sources.

The third phase, also called the binding phase, matches identifiers in the code with received named symbols from the previous phase. Because the processing of a method body is not dependent on other method bodies since the code only uses already known declarations, Roslyn makes this phase concurrent. The result of the phase is a *bound tree* where all identifiers refer to the named symbols. A method binding itself is a complicated procedure consisting of many subtasks such as *overload resolution* or mentioned method type inference, which algorithm is described in detail in the previous section.

The binding is divided into a chain of binders, taking care of smaller code scopes. One purpose of the binders is the ability to resolve an identifier to the named symbol if the referred symbol lies in their scope. If they can't find the symbol, they ask the preceding binder. The process of finding referred symbols is called *LookUp*. Examples of binders are `NamespaceBinder` resolving defined

top-level entities in the namespace scope, **ClassBinder** resolving defined class members, or **MethodBinder** binding method bodies. The last mentioned binder sequentially iterates body statements and matches identifiers with their declarations. Statement and expression binding are important steps that are related to type inference. An important observation is that statement binding doesn't involve binding of the following statements, which can be referred to as backward binding. The consequence is that C# is not able to infer types in the backward direction. An example can be the usage of the **var** keyword in variable declarations, which has to be used always with initializing value. If C# would allow backward binding, we could initialize the variable later in one of the following statements which would determine the type of the variable.

The preceding step before method type inference is overload resolution, part of **MethodCallExpression** or **ObjectCreationExpression** binding. As mentioned previously, method overloading allows to define multiple methods with the same name differing in parameters. So, when the compiler decides which method should be called, it has to resolve the right version of the method by following language rules for method resolution. This step involves binding the method call arguments first and then deciding which parameter list of the method group fits the argument list the best. If the method group is generic and the expression doesn't specify any type arguments, method type inference is invoked to determine the type arguments of the method before the selection of the best candidate for the call. When the right overload with inferred type arguments is chosen, unbound method arguments requiring target type (for example already mentioned target-typed **new()** operator) are bound using corresponding parameter type.

Method type inference can occur for the second time if previously mentioned nullability analysis is turned on. Nullability analysis is a kind of flow analysis that uses a bound tree to check and rewrite already created bound nodes according to nullability. Because overloading and method type inference are nullable-sensitive, the whole binding process is repeated, respecting the nullability and reusing results from the previous binding. The required changes are stored during the analysis, and the Bound tree is rewritten by the changes at the end of the analysis.

## 2.3 Hindley-Millner type inference

C# method type inference is a restricted Hindley-Millner type inference which is able to work in C# type system. Since type inference in other languages like Rust or Haskell is based on the same principle, this section presents a high-level overview of Hindley-Millner type inference and its type system to formalize the C# type inference, compare it with Rust type inference formalization and propose possible extensions of current C# type inference based on these observations.

Hindley-Millner type system [23] is a type system for *lambda calculus* capable of generic functions and types. Lambda calculus contains four types of expressions given below which are described in the video series [4]. Expression is either a variable (2.1), a function application (2.2), a lambda function (2.3), or a *let-in*

clause (2.4).

$$e = x \quad (2.1)$$

$$| e_1 e_2 \quad (2.2)$$

$$| \lambda x \rightarrow e \quad (2.3)$$

$$| \mathbf{let} \ x = e_1 \ \mathbf{in} \ e_2 \quad (2.4)$$

The above-mentioned expressions have one of two kinds of types. *Mono* type is a type variable(2.5) or a function application(2.6) where  $C$  is an item from an arbitrary set of functions containing at least  $\rightarrow$  symbol taking two type parameters which represents a lambda function type. The second kind is *Poly* type, which is arbitrary type with possible preceding  $\forall$  operator 2.8, bounding its type variables.

$$mono \ \tau = \alpha \quad (2.5)$$

$$| \ C \ \tau_1, \dots, \tau_n \quad (2.6)$$

$$poly \ \sigma = \tau \quad (2.7)$$

$$| \ \forall \alpha . \sigma \quad (2.8)$$

A context( $\Gamma$ ) contains bindings of an expression to its type which are described by pairs of expression and its type using the  $x : \tau$  syntax. An assumption is than described as a typing judgment shown in the  $\Gamma \vdash x : \tau$  syntax meaning "In the given context  $\Gamma$ ,  $x$  has the  $\tau$  type".

The H-M deduction system gives the following inference rules, allowing to deduce the type of an expression based on the assumption given in the context. The syntax of a rule corresponds with what can be judged below the line based on assumptions given above the line. The rules can be divided into two kinds. The first four rules give a manual on what types can be expected by applying the mentioned expressions of lambda calculus. The two last rules allow to convert Poly types to Mono types and vice-versa.

$$\begin{array}{c} \frac{x : \sigma \in \Gamma}{\Gamma \vdash x : \sigma} [Variable] \\ \frac{\Gamma \vdash e_0 : \tau_a \rightarrow \tau_b \quad \Gamma \vdash e_1 : \tau_a}{\Gamma \vdash e_0 e_1 : \tau_b} [Function \ application] \\ \frac{\Gamma, x : \tau_a \vdash e : \tau_b}{\Gamma \vdash \lambda x \rightarrow e : \tau_a \rightarrow \tau_b} [Function \ abstraction] \\ \frac{\Gamma \vdash e_0 : \sigma \quad \Gamma, x : \sigma \vdash e_1 : \tau}{\Gamma \vdash \mathbf{let} \ x = e_0 \ \mathbf{in} \ e_1 : \tau} [Let \ clause] \\ \frac{\Gamma \vdash e : \sigma_a \quad \sigma_a \sqsubseteq \sigma_b}{\Gamma \vdash e : \sigma_b} [Instantiate] \\ \frac{\Gamma \vdash e : \sigma \quad \alpha \notin Free(\Gamma)}{\Gamma \vdash e : \forall \alpha . \sigma} [Generalize] \end{array}$$

H-M type inference is able to find the type of every expression of a completely untyped program using only these type rules. Although, there exist several algorithms for the inference 2.15 shows only the W algorithm since it is closely related

```

1  fn Infer( $\Gamma$ , expr):
2      switch(expr):
3          expr isLike 'x'  $\rightarrow$  return ({}, Instantiate(expr))
4          expr isLike ' $\lambda x \rightarrow e$ '  $\rightarrow$ 
5               $\beta$  = NewVar()
6              ( $S_1$ ,  $\tau_1$ ) = Infer( $\Gamma + x: \beta$ , e)
7              return ( $S_1$ ,  $S_1\beta \rightarrow \tau_1$ )
8          expr isLike ' $e_1e_2$ '  $\rightarrow$ 
9              ( $S_1$ ,  $\tau_1$ ) = Infer( $\Gamma$ ,  $e_1$ )
10             ( $S_2$ ,  $\tau_2$ ) = Infer( $S_1\Gamma$ ,  $e_2$ )
11              $\beta$  = NewVar()
12             ( $S_3$ ,  $\tau_1$ ) = Unify( $S_2\tau_1$ ,  $\tau_2 \rightarrow \beta$ )
13             return ( $S_3S_2S_1$ ,  $S_3\beta$ )
14          expr isLike 'let x =  $e_1$  in  $e_2$ '  $\rightarrow$ 
15              ( $S_1$ ,  $\tau_1$ ) = Infer( $\Gamma$ ,  $e_1$ )
16              ( $S_2$ ,  $\tau_2$ ) = Infer( $\Gamma + x: \text{Generalize}(S_1\Gamma, \tau_1)$ ,  $e_2$ )
17              return ( $S_2S_1$ ,  $\tau_2$ )

```

Figure 2.15:  $W$  algorithm

to C# and Rust type inference. Inputs are the context  $\Gamma$  and an expression which type has to be inferred. The process consists of systematic traversing the expression from bottom to top and deducing the type of sub-expressions following the mentioned rules. The algorithm contains the **Instantiate** method which replaces quantified type variables in the expression with new type variables, the **Generalize** method replacing free type variables in the expression with quantified type variables, and the **Unify** method, also known as *unification in logic*. Unification is an algorithm finding a substitution of type variables whose application on the unifying types makes them identical. Outputs of this algorithm are the inferred type with a substitution used for the algorithm's internal state.

Relations between this algorithm and C#, Rust type inference will be discussed in detail later, although there can be noticed that the unification part of this algorithm is the same as method type inference mentioned in the C# section where the substitution represents inferred type arguments of the method which parameter types were unified with corresponding argument types.

H-M type system, doesn't allow subtyping known from Rust or overloading known from C#.

A basic principle of extending H-M type inference by subtyping is described in Parreaux's work [26], where instead of accumulating type equivalent constraints, it accumulates and propagates subtyping constraints. These subtyping constraints consist of a set of types, which have to be inherited by the constrained type variable, or the variable has to inherit them.

Extending H-M type inference by supporting overloading is mentioned in Andreas Stadelmeier and Martin Plümcke's work [25]. An important thought behind this paper is to accumulate two types of type variable constraint sets. Constraints observed from a method call are added into one *AND-set*. When the method call has multiple overloads, the *AND-sets* are added to the *OR-set*. After accumulating these sets, all combinations of items in *OR-sets* are generated and

solved by type inference. For each method overload participating in type inference, it makes a type inference containing constraints obtained only from the overloaded method, excluding constraints obtained from other overloads. This algorithm can be improved by excluding overloads that can't be used in the method call to save the branching. However, in the worst case, it still takes exponential time to infer types.

## 2.4 Rust type inference

Rust is a strongly typed programming language developed by Mozilla and an open community created for performance and memory safety without garbage collection. Besides its specific features like traits or variable regions, it also has advanced type inference, which is now described in a high-level perspective to get inspiration for the proposed C# improvement.

Figure 2.16 shows a significant difference between C# type inference and global Rust type inference. There is the `a` variable declaration initialized by the `Vec<T>` generic type which type argument is going to be inferred. The second statement calls the `push` method on the `a` variable, which is also generic and takes an argument of the `T` type. Since `1` value is passed into this call, `T` is inferred to be the `i32` type and the type argument of the creating vector becomes `i32`. An interesting behavior regarding the type inference is that it infers the type of creating object used in the first statement using information obtained from the second statement.

```
let mut a = Vec::new();
a.push(1);
```

Figure 2.16: Rust type inference example.

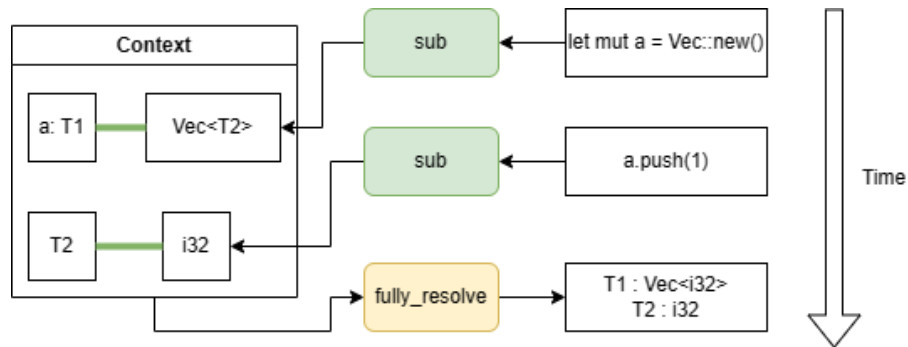

Figure 2.17: Rust type inference

This global type inference is possible thanks to a type inference context which is shared across multiple statements. Figure 2.17 shows a basic principle how the the context works. It starts with an empty context. As the compiler traverses a method body, it adds new type variables that have to be solved and constrains them by the types which they are interacting with. The figure demonstrates it by adding a new type variable `T1` representing a type of the `a` variable. It uses the `sub` function which adds the `Vec<T2>` subtyping constraint to the `T1` variable

represented by a thick green line. This constraint was obtained from a type of the initializing value `Vec::new()` which contains an unspecified type argument represented by a new `T2` type variable. Since, the initializing type can't be fully resolved because the constraint contains the `T2` unbound type variable it has to postpone the resolution. It passes the context to binding the next statement, where it collects another constraint about the `T2` type argument of the initializing value. The `sub` function is similar to the unification seen in the previous section, where it extracts the required bounds of unbound type variables by finding substitutions for type variables in order to make matching types containing the type variables equal. When there is enough information to resolve `T1` and `T2` type variables, they are resolved by finding an appropriate type for the type variable with respect to collected bounds. In the given example, the bounds contain only one type, so the type variables are resolved to them.

The mentioned sharing of context enables type inference to be backward, meaning that based on future type information, it is possible to infer already collected unbounded type variables. Besides sharing the context, there are other inference features that are missing in `C#` type inference and would be valuable. The first of them is type inference in object creation expressions, which doesn't exist in `C#`. The next regards collecting type constraints, which are obtained from a wider context than `C#` uses. For example, If a generic method containing a type variable in the return type is used as an assignment of an already typed variable, the type variable is constrained by the type of the target. Other features regard the inner implementation of type inference, which offers probing to constrain a type variable without influencing the context. There is a possibility of a snapshot that records all changes and can be used for backtracking and finding the right inferred type arguments. Although Rust type inference is more advanced in comparison with `C#`, it has to be considered language differences making type inference computation cost and difficulty relative to their features. As an example, the overloading can mentioned causing exponential time of type inference. Since Rust doesn't have overloading, the type inference can be more powerful without significant slowdown, which is not the case of `C#` as will be shown in the following chapter.

## 2.5 Github issues

The last section describes a process of proposing new `C#` language features and mentions already existing ideas, presented in the `C#` language repository, which are an inspiration to the thesis's proposed improvement.

The process of designing a new language feature starts with publishing an idea into discussions [17], where the `C#` community can comment on it. The idea contains a brief description of the feature, motivation, and design. Besides the idea, a new language feature requires a proposal, initially published as an Github issue, describing the feature in a way that can be later reviewed by the LDM committee. If the proposal sufficiently merits the discussions, it can be marked as a *champion* by a member of LDT for being discussed further in LDM. The state of a proposal is described by several milestones. The most important for the thesis is the *AnyTime* milestone, meaning that the proposal is not actively worked on and is open to the community to collaborate on it. At the time of

writing, a member of LDT recommended championed issue [12] regarding *partial type inference* to be investigated since it contains many related discussions with proposed changes but still doesn't have a required proposal specification which would allow to be discussed by the team. When a proposal has sufficient quality to be discussed by LDT, a member invites the proposer to make a *pull request* where further collaboration continues. If LDT accepts the proposal, it is added to the *proposals* folder in the repository for being added into the C# specification, and its future implementation (in Roslyn) will be shipped with the next C# version.

The recommended issue doesn't contain a specific idea of the improvement rather the scope of the improvement. The improvement suggests *partial type inference* which would allow to hint ambiguous type arguments which can't be inferred by a compiler instead of currently specifying the whole type argument list. Since it doesn't have any concrete way how to achieve it, there are presented related discussions directly or indirectly mentioned in the issue which partially suggest a possible solution.

The first discussion [2] mentions *default type parameters* introducing default type arguments, which are used when explicit type arguments are not used. Figure 2.18 shows a potential design of this feature where construing generic type **A** doesn't need a type argument since it uses **int** type as a default value.

```
var temp = new A();  
  
class A<T = int> {}
```

Figure 2.18: Default type parameters.

The next discussion [3] mentions *generic aliases* allowing to specify default values similar to the goal of the previous discussion by defining an alias to that type with option generic parameters. Figure 2.19 shows an example where there is the **StringDictionary** generic alias specifying the first type argument of the **Dictionary** class to be the **string** type, which simplifies the usage of the **Dictionary** type in scenarios where there are often used dictionaries with keys of the **string** type.

```
var temp = new StringDictionary<int>();  
  
using StringDictionary<TValue> = Dictionary<String, TValue>;
```

Figure 2.19: Generic aliases.

Discussion [5] mentions *named type parameters*, which are similar to named parameters of methods. The basic thought of this idea is being able to specify a type parameter for which an user provides a type argument by name. Figure 2.20 shows a generic method **F** with two type parameters. The current type inference forces to specify all type arguments in the **F** method call since it is not able to infer the **U** type. Named type parameters offer a way how to tell the compiler specific type parameters for which an user provides type arguments, **U** in this case, and letting the compiler infer the rest of the type parameters.

```
var x = F<U:short>(1);

U F<T, U>(T t) { ... }
```

Figure 2.20: Named type parameters.

Comments of the mentioned championed issue [12] propose several keywords that can be used in a type argument list for skipping type arguments, which can be inferred by the compiler and just providing the remaining ones. Figure 2.21 shows the `var` keyword for skipping the first type argument since it can be inferred from the argument list, and an user just specifies the second type argument, which can't be inferred by the compiler. The comments propose other options for keywords like underscore or whitespaces.

```
Foo<var, int>("string");

TResult Foo<T, TResult>(T p1){ ... }
```

Figure 2.21: Using `var` as inferred type argument.

Discussion [7] proposes *Target-typed inference*, where type inference uses type information of the target assigned by the return value. We can see the usage in Figure 2.22, where type inference determines that the return type has to be `int` type and uses that to deduce the type argument `T`.

```
object row = ...
int id = row.Field("id")

static class ObjectEx {
    T Field<T>(this object target, string fieldName)
    { ... }
}
```

Figure 2.22: Target-typed inference.

The next idea of improving type inference is given by the discussion [8], where type inference utilizes type information obtained from type constraints. A simple example of that can be seen in Figure 2.23, where `T1` can be deduced by using `T1`'s constraint and inferred type of `T2` forming inferred type `List<int>`.

```
var temp = Foo(1);

T1 Foo<T1,T2>(T2 item) where T1 : List<T2> {}
```

Figure 2.23: Type inference based on type constraints.

Discussion [9] mentions type inference of method return type known from Kotlin language. There is the usage in the following Figure 2.24, where the return type of the `Add` method is inferred to be `int` based on the type of the return expression.

```
public static Add(int x, int y ) => x + y;
```

Figure 2.24: Type inference of method return type.

An issue [6] proposes a way to compact type argument lists of identifiers containing inner identifiers with argument lists. The idea is demonstrated in the example 2.25, where the argument list of `A<T1>` type and the `Foo<T2>` method are merged, and the type arguments are split by a semicolon.

```
A.Foo<int;string>();  
  
static class A<T1> {  
    public static void Foo<T2>(){}  
}
```

Figure 2.25: Specifying type arguments in method calls (Reallocation).

The last discussion [1], which is mentioned here, regards *constructor type inference* enabling type inference for object creation expressions. The type inference can be seen in Figure 2.26, where the `T` type parameter of the `C<T>` generic type can be deduced by using type information from its constructor.

```
var temp = new C<_>(1); // T = int  
  
class C<T> { public C(T p1) {}}
```

Figure 2.26: Constructor type inference.

## 3. Problem analysis

Note: Describe the chapter

The chapter divides the analysis into four sections. The first section describes the scope of the improvement based on the mentioned championed issue recommended by LDT. The second section mentions a concrete motivation which leads us to the proposed improvement. The third section determines requirements based on the motivation, requirements given by proposing new language features, and Roslyn implementation internals. The fourth section describes the proposed language feature design, which is inspired by C# language feature ideas mentioned in the previous chapter and validated by the requirements. The last section mentions type inference improvements, whose implementation and proposal is not in the scope of this text, although their possible implementation is sketched for being inspiration of future improvements.

### 3.1 Scope

Note: Describe why we choose only a small part of the C# type inference

The previous chapter indicates that type inference is a complicated process, where even the current C# method type inference is difficult to understand. Hence, the thesis chooses a small part of C# where it improves and introduces the type inference and would be possible to reason about and implement in the scope of this text. The second reason for choosing a minor change is that introducing a completely new type inference in C# would rather have an experimental result, which would have a smaller chance of getting into production, which is different from the intention of this work. However, some more extensive changes in the type inference will also be mentioned to outline possible obstacles to introducing them in the C#.

Note: Specify the focus on partial type inference

The thesis focuses on the already-mentioned *partial type inference* proposal, which was recommended by a member of LDT and has a chance to be discussed in LDM and potentially accepted. Analysis of this improvement contains a consideration of existing ideas, their consequences on C#, and their difficulties in implementing them in Roslyn. Additionally, the work describes the relation to the Hindley-Millner formalization to express the strength of the type inference in a formalized way, which can be further used to compare it with other kinds of type inference in different programming languages and which decides the theoretical boundaries of the C# type inference.

### 3.2 Motivation

Note: What is partial type inference and why it is useful

Partial type inference focuses on hinting to the compiler ambiguous type arguments of generic type or method in situations where it can't deduce them. In the context of C#, the only type inference that infers type arguments is the

method type inference mentioned in the previous chapter. The weakness of the method type inference is the need to provide hints to the compiler. The following three real-world examples demonstrate common issues with method type inference weakness, which the thesis tries to solve.

Note: Weakness of current method type inference - target typing

The first weakness regards target typing, which was mentioned in the previous chapter. Suppose a hypothetical situation when a user queries an item from a database whose column is a point of interest. Figure 3.1 shows an example of code that uses the `fetch` method defined on a database type. The `data` variable represents data fetched from a database. Since a concrete form of data is unknown, the data has the type of `object` containing an internal representation of fetched data with the columns stored as fields. The `GetField` method enables one to read the variable's field of the given name with the supposed type given as a type argument. Suppose the fetched object contains the "name" field containing a string value. Now, a user wants to store the value in the `name` variable, which is explicitly typed. Even though the return type of the `GetField` method is known from the variable declaration, which also is the `TReturn` type argument of the method, the user still has to specify the type argument in the call. Generally, this problem consists of all type inferences, which depend on the target type. The target can be an argument of another method call or an assigning field. If the method type inference considers the target type, the user will not have to specify the `string` type argument in the `GetField` call.

```
object data = database.fetch();
string name = data.GetField<string>("name");
...
static class Extensions {
    static
    TReturn GetField<TReturn>(this object inst, string fieldName)
    {...}
}
```

Figure 3.1: Target-typed inference.

Note: Weakness of current method type inference - Constraints-based inference

The second weakness is noticeable in more advanced generic APIs, like testing frameworks, using type constraints containing the type parameters. Figure 3.2 shows a scenario of a simple test framework that defines the `Test` method parameterized by a type of input data and test case represented as type parameters `U` and `V`, respectively. The providing type argument representing the test case has to inherit the `TestCaseBase` base implementation, which is a generic type parametrized by a type of input data. This constraint gives type information about the `T` type parameter, which is related to the type of input data. However, the user has to specify type arguments in the `Test` call since the type inference doesn't consider this source of type information. If the compiler considers the constraint, the type arguments will be inferred, saving the type annotations.

Note: Weakness of current method type inference - all or nothing principle

There are also situations where even strong type inference is not enough.

```
Test<TestCaseBase<MyData>, MyData>(new MyData());
...
void Test<T, U>(U data) where T : TestCaseBase<U> {...}
```

Figure 3.2: Constraints-based inference.

Figure 3.3 shows a situation where the `log` method is parametrized by two type parameters that are obtained in the parameter types and hence inferable by the compiler. However, the `log` method call still has to specify type arguments because the `null` argument doesn't have concrete type information. In this case, the user always has to specify the second type argument, but the compiler can infer the first type argument. The thesis refers to this problem as *all or nothing* principle, which regards the obligation to specify all type arguments or none of them.

```
log<Message, Appendix>(new Message(...), null);
...
void log<T, U>(T message, U appendix) {...}
```

Figure 3.3: Uninferable type argument.

Note: Breaking changes - Possible improvement of method type inference

The first and the second weaknesses motivate us to extend the method type inference in order to consider a wider context for obtaining type information for the type arguments. This potential improvement is a problem for the compiler's back compatibility which was mentioned in the C# discussion [10]. New compiler versions should be back-compatible so that a new version does not change the behavior of the code compiled by the older version.

Note: Breaking changes - target-typing

Figure 3.4 shows the breaking change when method type inference starts to consider target types. Before the improvement, the `M` method call is resolved to the non-generic version of this method because type inference can't infer the `T` type argument. After the improvement, the type inference infers `T` to be the `int` type, which is more specific to the type of `1` argument than the `long` type. So now, the `M` method call refers to the generic version of this method and executes different code without any warning or error.

```
int name = M(1);
...
T M<T>(int p1) {...}
int M(long p2) {...}
```

Figure 3.4: Breaking change: Target-typed inference.

Note: Breaking changes - Constraints-based inference

Figure 3.5 shows a similar situation when the method type inference starts to consider type parameter constraints. Before the improvement, the `M` method call refers to the non-generic version of the method since the type inference can't infer the type argument of a generic version. After the improvement, the generic

version is inferred to have the `int` type argument and becomes to be more suitable for the overload resolution. So, the code behavior changed again because of compiling it with a different compiler's version.

```
M(1);  
...  
void M<T>(int p1) where T : List<int> {...}  
void M(long p2) {...}
```

Figure 3.5: Breaking change: Constraints-based inference.

Note: Possible method type inference improvement doesn't solve the third weakness

Besides the breaking change, the potential method type inference improvement to use a bigger context still doesn't solve our third example demonstrating a type parameter, which doesn't appear in parameter types, return type, and the type parameters' constraints. These obstacles give the reason for introducing a way to hint just ambiguous type arguments to the compiler.

Note: Partial type inference - reduces the first and second weakness

Partial type inference can reduce the first two weaknesses. Type arguments, which the method type inference can't infer, can be hinted in order to avoid specifying the whole type argument list. Let's now ignore why the underscore character is used and how inferred type variables are determined in the following example. The reasons behind that will be mentioned later. Figure 3.6 shows the usage of partial type inference applied in the second presented example regarding method type inference weaknesses. Although the first type argument of the `Test` method call must still be provided, the second argument is omitted by using the underscore character to determine an inferred type argument. The reduction of the first weakness is to isolate the insufficient type inference to type arguments that are directly influenced by it and infer the rest.

```
test<TestCaseDefault<MyData>, _>(new MyData());  
  
void test<T, U>(U data) where T : TestCaseDefault<U> {...}
```

Figure 3.6: Partial type inference: Reducing method type inference weakness.

Note: Breaking changes - solves the third weakness

The third motivation example confirms that partial type inference is not just a fix for missing type inference features but is needed when type arguments can't be inferred at all. Figure 3.7 demonstrates a usage of partial type inference where it omits the first type argument since it can be deduced from the first argument type and specifies the ambiguous type that can't be deduced.

```
log<_, Appendix>(new Message(...), null);  
  
void log<T, U>(T message, U appendix) {...}
```

Figure 3.7: Partial type inference: Solving the *all or nothing* problem.

Note: Constructor type inference - next motivation and improvement

Partial type inference doesn't regard only method type inference. It can also be introduced in other places. One of the places that seems to be good for that is object creation expression. Except for the already mentioned `new()` operator, no other type inference infers type arguments of a construing generic type. The usage of the type inference is limited since the `new()` operator requires a target type to infer the construing type. Figure 3.8 shows an example of the limitation, where the `new()` operator can't be used since the `IWrapper` target type is not the `Wrapper<int>` construing type. Hence, the user has to specify the whole type with the `int` type argument, despite the fact that it could be inferred using method type inference.

```
IWrapper a = new Wrapper<int>(1);

class Wrapper<T> : IWrapper { public Wrapper(T item) {...} }
```

Figure 3.8: C# wrapper class.

Note: Constructor type inference - Factory method workaround

In principle, object creation can be considered a special case of a method call with a side effect (creating the object), which already has method type inference. Figure 3.9 shows a workaround using the `Create` method, delegating the creation to the constructor call. Since the method call type arguments can be inferred, it allows the use of method type inference for inferring type arguments of construing type. However, this solution has disadvantages like the necessary boiler-plate and prohibition of using initializers.

```
IWrapper a = Create(1);

static Wrapper<T> Create<T>(T item) => new Wrapper<T>(item);
```

Figure 3.9: Workaround of constructor type inference.

Note: Constructor type inference - strength of method type inference

A possible solution would be to use method type inference in object creation expression. Although this solution would be simple to implement, class type parameters are more likely not to be used in constructor parameter types, which makes the method type inference useless. Besides that, options for inferring type arguments of construing type are not limited by not introducing breaking changes since there is no type inference at all. So, there is a possibility of introducing an even stronger type inference, which could be one day introduced in the method type inference when there would be a way to make breaking changes in the new compiler version. Figure 3.10 shows an example of such a generic class whose all type parameters are not used in the constructor. Because of that, extending the potential method type inference to be used in object creation expressions would be useless since the `TLogger` can't be inferred only from parameter types.

Note: Constructor type inference - the first weakness solution

Introducing improved type inference based on method type inference would solve the mentioned issues. Figure 3.11 shows a potential usage of that type

```
class Algorithm<TData, TLogger> where TLogger : Logger<TData>
{ public Algorithm(TData data) { ... } }
```

Figure 3.10: Use case using type parameter constraints.

inference in the first case regarding the Wrapper class where an underscore is used to represent inferred type argument. The inference uses the parameter type of the constructor to infer the T parameter type which is `int`.

```
IWrapper a = new Wrapper<_>(1);

class Wrapper<T> : IWrapper { public Wrapper(T item) {...} }
```

Figure 3.11: Constructor type inference: Wrapper.

Note: Constructor type inference - better method type inference

Figure 3.12 shows a potential improvement of the type inference. The first statement of initializing the `alg` variable uses type inference, leveraging `TLogger`'s constraint to determine its type. The second statement demonstrates the possibility of having a nested underscore, which allows to more specify the type argument.

```
var alg = new Algorithm<_, _>(new MyData());
var algWithSpecialLogger =
    new Algorithm<_ , SpecialLogger<_>>(new MyData());

class Algorithm<TData, TLogger>
    where TLogger : Logger<TData>
{ public Algorithm(TData data) { ... } }
```

Figure 3.12: Constructor type inference: stronger method type inference.

From now on, thesis calls *constructor type inference* for introducing such a type inference.

### 3.3 Requirements

Note: intro

This section mentions requirements that have to be fulfilled by the improvement to be likely discussed by LDM.

Note: Describe requirements given by back compatibility

**Back compatibility** is one of the most important requirements for new language features. The improvement shouldn't introduce a breaking change. However, this requirement is sometimes too strict for improvements, which would be very beneficial, and its breaking change would appear in cases that seem to be rare in the code. These improvements can break back compatibility by providing additional warnings or errors alerting a user of possible code behavior changes. Figure 3.13 shows an introduced breaking change when record classes were added

into the C# language. Before the change, the `B` identifier referred to a method without parameters and returned the `record` type. After the change, the `B` identifier refers to a new record type declaration. There is an example where the breaking change can appear when there is a type with the `record` name. These situations are uncommon, and the improvement benefit was big enough to be added to the language. The possible breaking change is notified to the user by a compilation error.

```
class record {}
class A {
    record B(){...}
}
```

Figure 3.13: C# record class breaking change.

Note: Describe requirements given by motivation

**Convenience** is a key requirement to make the improvement useful. Regarding partial type inference, the improvement should propose a convenient way to skip ambiguous type arguments. The way should also be possible to use in different places where skipping type arguments could yield an advantage, like type variable declaration or casting to a different type. Constructor type inference should be advanced enough to cover the mentioned examples.

Note: Describe requirements given by Future improvements

**Extensibility** would make the improvement open for new features that can be needed in future language versions. The improvement should consider possible future improvements and not be a blocker for them.

Note: Describe requirements given by Roslyn

**Performance** is a critical section of Roslyn, which is one of the main goals of this project. The time complexity added by the thesis's improvement shouldn't be too big in order to not slow the compilation process.

## 3.4 Language feature design

Note: Intro

This section describes the language design of the proposed improvement. It discusses existing ideas of the partial type inference and combines them to form the proposed design. Then, it adjusts method type inference algorithm to handle partially specified type arguments and introduces constructor type inference, which extends method type inference algorithm.

Note: Discuss mentioned ideas

The mentioned ideas can be categorized into three groups. The first group consists of target-typed inference and type inference based on type constraints, which improve method type inference algorithm. The second group consists of default type parameters, generic aliases, named type parameters, using `char` as inferred type argument, and relocation, which regards partial type inference. The third group consists of constructor type inference and type inference of method return type, which introduce type inference in new C constructs. Method return

type inference is not in the scope of this work, although it is mentioned in the next section as a future improvement that will be difficult to implement. The first group is discussed in relation to constructor type inference, where potentially applied method type inference can be improved without introducing breaking changes. The second group is discussed in relation to partial type inference, which is an objective of the championed issue.

### 3.4.1 Partial method type inference

Discussions regarding partial type inference can be further divided into two groups. The first group provides hints in type parameter declarations, which are done by default type parameters. Since it has to be done in the declaration, partial type inference wouldn't work with already existing code without adjusting it. For this reason, the work excludes the idea.

The second group provides hints through the usage. Generic aliases don't work for methods, and also, it doesn't seem to be useful when the inferred type arguments don't represent some common specialization of generic type. An example of the specialization is `StringDictionary<TValue>` mentioned in the previous chapter.

Named type parameters are excluded since providing that would be an uncommon new feature that has no equivalent in other well-known languages like Java, C++, Kotlin, and Rust. We believe it would be confusing to introduce it to the users since it is a controversial change.

Relocation doesn't solve the problem of specifying all type arguments. It just compacts type argument lists into one.

The last discussion regards using `char` as an inferred type argument, which is a core of the proposed design for the following reasons. It is already used in different languages, like a star in Kotlin and Java or an underscore in Rust and F#. So, it is more common and intentional than previously mentioned ideas. It introduces no or at least minimal syntax changes into the language, which makes the usage simple, and it solves the problem of specifying all type arguments.

#### 3.4.1.1 Choosing the syntax

The choice of the syntax is based on five use cases where the expression of inferred type argument can be used or could be used in the future. Table 3.1 shows examples of these usages, which identify necessary syntax requirements.

Generic method call	<code>Foo&lt;{SYNTAX}&gt;(arg1, arg2,...)</code>
Object creation expression	<code>new Bar&lt;{SYNTAX}&gt;(arg1, arg2,...)</code>
Variable declaration	<code>Bar&lt;{SYNTAX}&gt; temp = ...</code>
Array type	<code>{SYNTAX} []</code>
Inferred type	<code>{SYNTAX}</code>

Table 3.1: Use cases containing syntax for inferred type argument.

**Generic method call** use case represents a situation where the syntax is used during a generic method call.

**Object creation expression** represents the usage in the construction of generic type.

**Variable declaration** represents the potential usage in the variable type declaration, which is not in the scope of this work. However, it is a natural continuation of partial type inference extension where the inferred type arguments are determined by the surrounding context.

**Array type** has a different syntax of type argument list specifying a type of the contained elements. The type of the elements can also be inferred, and the proposed syntax has to offer a convenient way to express an array type with the inferred element type.

**Inferred type** doesn't have to be contained only in the type argument list. The previous chapter presented the `var` keyword used in the variable declaration, whose type is determined by the type of initializing value. C# also offers a discard pattern [16] represented by an underscore, which is commonly used as a placeholder for variables that are not intentionally used in the code. Since type argument inference relates to that, the syntax should be at least aligned with already existing related syntax. The alignment will help the syntax to be naturally used without using language documentation.

There are several syntax that can be used for inferred types. The work presents the most relevant syntax that appeared in the mentioned ideas and comments on the advantages and disadvantages for each variant.

**Diamond operator** is represented by a pair of two angle brackets `<>`. It is used as an empty type argument list determining that the type name or method name is generic.

Figure 3.14 demonstrates the usage in generic method calls of `Foo1` and `Foo2`. The declarations of these methods are not important for the purpose of showing the pros and cons. Calling the `Foo1` method with an empty argument list doesn't make much sense since method type inference is enabled by default without using angle brackets. Calling the `Foo2` method with nested usage of the diamond operator allows limited partial type inference when the diamond operator is used inside the type argument list. The `Bar<>` type partially hints to the compiler the generic type name without specifying the type arguments. However, the usage is problematic when there are multiple generic types with the same name since it can cause ambiguity between them. This problem is described in the next example.

```
Foo1<>(arg1, arg2, arg3);  
Foo2<Bar<>, int>(arg1, arg2, arg3);
```

Figure 3.14: Diamond operator - generic method call.

Figure 3.15 shows the usage in object creation expression. The first statement containing `Bar<>` name has the advantage of expressing the will to infer the type's type arguments, which is necessary in comparison to the previous example since the object creation doesn't offer type inference. If the type inference were potentially turned on by default, it would introduce a breaking change. However, there is also a disadvantage of the usage since it doesn't specify the arity of the generic type. If there were multiple generic types differing in arity, it would complicate

the already mentioned overload resolution phase since all constructors from these generic types would have to be considered. The process would be computationally demanding. A possible solution would be the following restriction. Usually, there is not more than one generic type with the same name. So when there is just one type of that name, the diamond operator would be allowed to use it since the name determined one specific generic type. In the example, `Baz<>` would refer to `Baz<T1, T2>` generic type since there is no other generic type with the same name, causing the ambiguity.

```
new Bar<>(...);
new Baz<>(...);

class Bar { ... }
class Bar<T1> { ... }
class Bar<T1, T2> { ... }

class Baz<T1,T2> { ... }
```

Figure 3.15: Diamond operator - object creation expression.

The third example is shown in Figure 3.16, where the generic `Wrapper` class is used to specify the wrapping generic type. However, it doesn't offer to specify any type arguments, which is limiting when the compiler can't infer all of them.

```
Wrapper<> temp = ...
```

Figure 3.16: Diamond operator - variable declaration.

Figure 3.17 shows the operator as an indicator of the inferred element of the array type. Since there isn't a known popular language similar to C#, which would contain a similar construct, the usage is considered to be unintentional for most of the users.

```
<>[] temp = ...
```

Figure 3.17: Diamond operator - array type.

Similar conclusions are made in the last example in Figure 3.18 where the `<>` operator has the same functionality as the already existing `var` keyword.

```
<> temp = ...
```

Figure 3.18: Diamond operator - inferred type.

**Whitespace separated by commas** is the next proposed syntax, which would allow skipping inferred type arguments and specify just the ambiguous. It would also determine the arity of type, which is important for the type name look-up phase of the compiler. A natural choice for the separator is commas since it is widely used. Another advantage is that this syntax is already used when working

with C# reflection. An example is the following expression `typeof(Dictionary<,>),` which returns a class describing the `Dictionary` type.

Figure 3.19 shows the usage when the `Foo1` generic method is called by skipping the first and the last type argument, which is inferred by the compiler. However, the syntax seems to be messy when it is used in generic methods with many generic type parameters, as can be seen in the `Foo2` method call. Similar thoughts regard the second and third use case.

```
Foo1<, string, List<>, >(arg1, arg2, arg3);  
Foo2<,,,int,,>(arg1, arg2, arg3);
```

Figure 3.19: Whitespace - generic method call.

The usage with array type seems to be unintentional and would cause changes in the compiler parser. Figure 3.20 shows the syntax to express the inferred type of array's element.

```
[] temp = ...  
Foo<, [], >(arg1, arg2)
```

Figure 3.20: Whitespace - array type.

The last use case regarding using the whitespace as an inferred type would probably cause problems with determining declarations of variables. Figure 3.21 shows a situation where the compiler can't determine if it is a variable declaration or a variable assignment. Although it could be solved by investigating the surrounding context, we consider that the code comprehension would get worse.

```
temp = ...
```

Figure 3.21: Whitespace - inferred type.

**Underscores separated by commas** is commonly used in other programming languages like F# or Haskell to represent inferred type arguments, or as a placeholder for discarding variables that are intentionally not used. This is considered as a big advantage. A disadvantage is the introduction of breaking change because C# allows the underscore as a type identifier. However, that seems to be rather uncommon in the code. It seems to be less messy than the previous syntax when a generic type contains many type parameters, as shown in Figure 3.22.

```
new Bar<_, _, List<_>, _,_>(arg1, arg2, arg3);
```

Figure 3.22: Underscore - object creation expression.

The usage with array type also seems to work even if it can still be considered uncommon. Figure 3.23 shows the usage where we think that the syntax intentionally expresses the inferred type of array's elements.

The last use case is shown in Figure 3.24 where it clashes with the already existing `var` keyword.

```
_[] temp = ...
```

Figure 3.23: Underscore - array type.

```
_ temp = ...
```

Figure 3.24: Underscore - variable declaration.

**var keywords separated by commas** are another natural option of the syntax. The big advantage of the syntax is the already used `var` keyword in the variable declaration, whose meaning is coherent with inferred type arguments. However, it starts to raise the question if it brings the advantage of saving keystrokes. Figure 3.25 shows a usage of the syntax, which is considered to be unnecessarily long.

```
Foo<var, string, List<var>, int>(arg1, arg2, arg3);
```

Figure 3.25: `var` - generic method call.

**Something else separated by commas** doesn't make a lot of sense because it needs to assign new meaning to that character in comparison with an underscore, the `var` keyword, the `<>` operator, or `<, , >` syntax. An asterisk can be considered. However, it can remind a pointer in the context of unmanaged C# code.

**Conclusion** The thesis chooses the underscore as a placeholder for inferred type argument since the meaning of this character is related to the intention. It also seems to be the shortest and synoptical way to skip inferred type arguments. The possible breaking change is not an obstacle in this situation since a similar decision was made for the `var` keyword, and the situation where it can occur seems to be rare. Problems with the potential future extension where the underscore can represent inferred type in the variable declaration would be prohibited to not mix it with the `var` keyword. Although the diamond operator is not very useful in a generic method call, it makes sense in object creation expression. The usage and analysis of that is covered by this work as well.

2.4	C# anonymous functions. . . . .	8
2.5	C# collection initializer. . . . .	8
2.6	Keyword <code>var</code> . . . . .	9
2.7	Operator <code>new()</code> . . . . .	9
2.8	Method type inference. . . . .	9
2.9	Phases of Method Type Inference . . . . .	11
2.10	<i>Explicit parameter type inference, Output type inference</i> . . . . .	12
2.11	<i>Exact inference, Upper-bound inference, Lower-bound inference</i> . . . . .	13
2.12	Fixing of type variables . . . . .	14
2.13	Array type inference. . . . .	14
2.14	Roslyn architecture . . . . .	15
2.15	<i>W</i> algorithm . . . . .	18
2.16	Rust type inference example. . . . .	19
2.17	Rust type inference . . . . .	19
2.18	Default type parameters. . . . .	21
2.19	Generic aliases. . . . .	21
2.20	Named type parameters. . . . .	22
2.21	Using <code>char</code> as inferred type argument. . . . .	22
2.22	Target-typed inference. . . . .	22
2.23	Type inference based on type constraints. . . . .	22
2.24	Type inference of method return type. . . . .	23
2.25	Specifying type arguments in method calls (Reallocation). . . . .	23
2.26	Constructor type inference. . . . .	23
3.1	Target-typed inference. . . . .	25
3.2	Constraints-based inference. . . . .	26
3.3	Uninferable type argument. . . . .	26
3.4	Breaking change: Target-typed inference. . . . .	26
3.5	Breaking change: Constraints-based inference. . . . .	27
3.6	Partial type inference: Reducing method type inference weakness. . . . .	27
3.7	Partial type inference: Solving the <i>all or nothing</i> problem. . . . .	27
3.8	C# wrapper class. . . . .	28
3.9	Workaround of constructor type inference. . . . .	28
3.10	Use case iusing type paraemter constraints. . . . .	29
3.11	Constructor type inference: Wrapper. . . . .	29
3.12	Constructor type inference: stronger method type inference. . . . .	29
3.13	C# record class breaking change. . . . .	30

3.14	Diamond operator - generic method call. . . . .	32
3.15	Diamond operator - object creation expression. . . . .	33
3.16	Diamond operator - variable declaration. . . . .	33
3.17	Diamond operator - array type. . . . .	33
3.18	Diamond operator - inferred type. . . . .	33
3.19	Whitespace - generic method call. . . . .	34
3.20	Whitespace - array type. . . . .	34
3.21	Whitespace - inferred type. . . . .	34
3.22	Underscore - object creation expression. . . . .	34
3.23	Underscore - array type. . . . .	35
3.24	Underscore - variable declaration. . . . .	35
3.25	<b>var</b> - generic method call. . . . .	35

# List of Tables

2.1	Description of used properties. . . . .	10
3.1	Use cases containing syntax for inferred type argument. . . . .	31
